Theory Sine Sweep Vs Random

Sine vibration testing applies a single frequency to a test item and selectively excites resonant structures within the device. In a swept sine test a vibration sine tone is ramped up and down through a range of frequencies and for

Random vs. Sine.
Sinusoidal vibration tests typically are not as helpful as random testing in certain condition since a sine test focuses on single frequency consistently. A random vibration test, however, always excites all the frequencies within a defined spectrum. Wayne Tustin's had a good lay person's description of random vibration:

pans through a range of frequencies rather than just one. The motion of the shaker is sinusoidal; however, the frequency of the vibration increases or decreases throughout the test. Therefore, the product is tested over a range of frequencies.

The random vibration test is supposed to simulate the expected environment. The sine sweep test is only a 1G sweep through 0-500 Hz. As I explained, this 1g sine sweep will be done before and after the random vibration test. So natural frequencies and damping ratios will be recorded.

Sine-on-Random (SoR) vibration testing contains sine tones that are superimposed on a low level of broadband random vibration. The sine tones can be fixed frequency or sweeping. If they are sweeping, they are normally very narrow frequency bands.
